Surgical Treatment of Glioblastoma Multiforme Localized in the Motor Area of the Brain Using the Technique of Cortical Electrostimulation

ABSTRACT

AIM: Glioblastoma multiforme in the motor area is the surgical challenge because of the need for more radical resection in order to extend the life of the patient, and the risk that radicalism could lead to additional neurological deficit.

MATERIAL and METHODS: We present series of 26 patients with glioblastoma multiforme localized in and around the motor area, who were hospitalized from October 2004 to February 2009. During all operations, we conducted electrostimulation display area of the brain, to the anatomical location of M1 segment of the motor cortex.

RESULTS: Distance of the central sulcus in relation to the coronary suture, measured by magnetic resonance imaging (MRI) was 18.38 mm ± 9.564 mm. The volume of electricity required for a motor response was mean 8.79 ± 1.484 mA, with increasing distance from the coronary suture the amperage required to explicit motor responses decreased. The difference (mm) between the distance from the coronary suture measured using MRI and distances measured electrostimulation smaller and power consumption was less (F = 13.285, p <0.01).

CONCLUSION: The method of cortical cerebral cortex electrostimulation is simple and safe method and a binding protocol to the patient safe operation glioblastoma multiforme localized in the motor area of the brain.

KEYWORDS: Brain, Electrostimulation, Glioblastoma multiforme, Motor cortex

INTRODUCTION

Malignant gliomas cause a total of 2.5% of cancer deaths per year and are the third cause of death from cancer at the age of 15 to 34 years of age (13,22). Glioblastoma multiforme are most malignant form of primary brain tumors in adults, predominantly localized in the hemisphere, in 24% were localized in and directly around the motor area of the brain (14,28). Neurosurgeons, brain tumors consider as active lesions for which they need to find a solution, because the smaller the rest of tumor tissue after surgical resection, the longer period of survival (26,23). Therefore it is necessary to know the natural course of brain tumors in their initial, intermediary and terminal stage (30). Despite the maximum radical surgical resection and additional oncological protocols use combination of radio and chemotherapy, overall survival for patient with glioblastoma multiforme is between one and two years (17,15). The functions
of human cortex, despite the anatomical boundaries are organizationally related and surgical resection can basically considered a breach of Preoperative and intraoperative brain mapping, separating the normal from the abnormal function and allows resection of lesions that previously could not even imagine (8). Current studies recommend standard use of intraoperative electrical stimulation of the brain during operations in eloquent brain zone, a method that improves postoperative functional outcome (5, 4, 16, 31). Direct cortical electrostimulation was safe, accurate and easy to perform method for identification of eloquent cortical and subcortical field (2, 18, 7).

MATERIAL and METHODS
Our study included a total of 26 patients with supratentorial glioblastoma multiforme localized in and around the motor area in front of the central sulcus, who were hospitalized at the Institute of Neurosurgery, Clinical Center of Serbia in Belgrade from October 2004 to February 2009. Assessment of pre and post operative status of the patients was validated Karnofski index. From the study we excluded patients with recurrent tumors and patients whose Karnofski index at admission was less than 70. In order to achieve a clear preoperative orientation, especially in the present cases, infiltrative tumor growth, with no visible boundaries to the surrounding brain tumors, we performed to measure the distance of the central sulcus (the longest in the high parietal sulcus sections) in relation to the coronary suture on MRI images, based on diagnosed and planned operations. All patients were operated under general anesthesia using the general intravenous anesthesia, without the addition of volatile anesthetics. For the induction of anesthesia in the bolus propofol (1-2mg/kg) and fentanyl (5-10μg/kg) were used. Anesthesia was maintained with continuous administration of propofol (75-125μg/kg). Intraoperative analgesia was achieved by remifentanil (0.25 mg / kg / min). Neuromuscular blockers were used only for intubation (rocuronium from 0.3 to 0.4 mg / kg or mivacurium 0.2 mg/ kg) but not during the surgery (neuromuscular blockade was effective only 15-25 minutes during intubation). Prophylactically every patient’s was provided by preoperative peroral antibiotic (2g Nilacef to 12 pm), dexamethasone in a single dose of 8 mg iv in 6 hours and anticonvulsant therapy Mazepin 3x200mg. During all operations electrostimulation was conducted on display area of the brain to reach the anatomical location of M1 segment of the motor cortex (Figure 1). For electrical stimulation of the cortex were used 3-contact strip electrodes (AD-Tech® strip electrodes, AD Tecnica, WI, USA). Upon identifying the motor fields the distance from the coronary suture was measured and performed by comparison with the values obtained from the preoperative measurement of the distance of the central sulcus of the coronary suture on the MRI image. The data were processed by computer aided SPSS 12.0 software package.

RESULTS
Histopathologic analysis confirmed the existence of glioblastoma multiforme tumors forms in 26 cases. The average age of patients with glioblastoma multiforme was 55.38 ± 14.020 years. In all cases the diagnosis of intracranial expansive lesion located in the region of the central sulcus of the brain was made by recording the nuclear magnetic resonances imaging (MRI). In 42.3% (11) findings of the lesions were localized in the left supratentorial hemisphere, and 57.7% (15) in the right supratentorial hemisphere. In order to achieve a clear preoperative orientation, especially in the present cases, infiltrative tumor growth, with no visible boundaries to the surrounding brain tumors, we performed to measure the distance of the central sulcus (the longest in the high parietal sulcus sections) in relation to the coronary suture on MRI.
images, based on diagnosed and planned operations. The average distance of the central sulcus in relation to the coronary suture was 18.38 mm ± 9.564 mm; minimum distance amounted to 7 mm and a maximum of 42 mm. (Table I) All patients were operated (26) under general anesthesia, and during all operations we conducted electrostimulation display area of the brain for anatomical location of M1 segment of the motor cortex (Figure 2). The average value of electric current intensity needed to obtain motor responses was 8.79 ± 1.484 mA (min. 6mA, max. 12mA). Longer distance from the coronary suture imply decreased strength of current intensity required to explicit motor responses \( r = -0.574, p <0.01 \)

Based on these results mathematical regression model is proposed assuming the necessary electric current needed to obtain motor responses during ES M1 field. The proposed regression model showed an absolute statistical reliability \( F = 29.030, p <0.01 \) (Figure 3).

The regression model is: \[
\text{Current strength} = 10.473 \times \text{distance from the coronary suture}.
\]

Analyzed was the variable representing the difference in millimeters between the distance of the central sulcus of the coronary suture measured using MRI and distance M1 zone measured from the coronary suture electrostimulation (ES) (Figure 4).

Calculated correlation coefficient is: \( r = -0.438, p <0.01 \).

**Figure 3:** The relation of electric potential and the distance the motor zone of the coronary suture.

**Figure 4:** The difference distance from the coronary suture zone M1 MRI / ES.

The difference (mm) between the distance from the coronary suture measured using MRI and distances measured electrostimulation smaller and power consumption was less \( F = 13.285, p <0.01 \).

Regression model is: \[
\text{Rated current} = 9.931 \times \text{difference radiographic / electrograph. tool in mm} \quad (F = 13.285, p <0.01).
\]

The average strength of electric current needed to explicit motor responses in patients suffering from glioblastoma multiforme was 8.115 ± 1.479 mA. Statistical analysis showed a statistically significant \( p <0.05 \) lower amperage required for the identification of motor areas of tumors where the degree of surgical resection was a subtotal to the level of reduction (9 - 34.7%) - 8.273 ± 1.162 mA compared the radical operation (17 - 65.3%) - 9.079 ± 1.549 mA (Table II).

Single view in relation to the histological group of tumors, show a numerical increase of Karnofski index (CI) after surgery compared to the situation before surgery. The mean value of CI before surgery for glioblastoma multiforme was 75.38 ± 8.593 and postoperative 79.23 ± 8.910 (Table III).

**DISCUSSION**

Surgery of lesions localized in the motor cortex is a challenging part because of the accompanying risk of de novo occurrence of motor deficit. Intrinsic tumors may affect cortical and subcortical structures, with no signs of functional deterioration (Figure 4). On the other hand a clear presentation
of the vast area of the tumor in a patient without neurological deficits present before surgery may not be a guarantee that the tumor can be removed radically without the possibility of subsequent motor deficit (25). Group of authors is of opinion that the length of survival after surgery are directly dependent on the degree of resection as the low grade and high grade gliomas in the brain, and if the resection include the supplementary motor field can be the full iniencephaly (2). Electrical stimulation of the cortex in infiltrating glioma of the cortex localized in the motor cortex prevents damage to functionally important parts of the cortex and allows resection of the primary cortex and the degree of surgical radicality. In 11 cases patients had delayed motor deficit in the period of 8 hours to 3 days after surgery, which completely recovered within three months (29). Duffau et al. indicate the effect of glioma infiltration on local brain function in three patients who underwent reoperation within 12 to 24 months after the first surgery (8). All three patients had neurological deficits preoperatively, operated from low grade glioma localized in functionally important brain motor area. For each operation, the procedure used electrical stimulation of the cortex and functional mapping - identification of motor areas of the brain. Since the tumors were localized in the sensorimotor cortex in all three cases underwent subtotal resection. All three patients were reoperated 12-24 months later, re-electro cortex and functional mapping of motor areas. In all three cases in the repeated surgery was performed a radical resection without additional neurological deficits. Duffau recommends the standard use of intraoperative electrical stimulation of the brain during operations in eloquent areas of the brain as a method which improves postoperative functional outcome (4, 5, 8, 6, 16, 31). Direct cortical electrostimulation is safe, accurate and easy to perform method for identification of eloquent cortical and subcortical field (2, 7, 18). Functional neural tissue can be detected inside the tumor which causes a limited surgical resection (19, 27). Modification in the spatial organization and direction of tumor growth can be caused by previous surgery and tumor itself can cause functional peritumoral reorganization of motor cortex with the absence of neurological deficit, although part of the eloquent area located within the boundaries of the tumor and / or induce compensatory function of other ipsilateral regions responsible for the same function (5, 6, 7, 19).

CONCLUSION

Direct electrostimulation of cerebral cortex is a reliable method for identification of motor areas of the brain, and a requirement for additional prevention - iatrogenic neurologic deficit. Schiffbauer and colleagues, comparing the difference in distance between the motor areas on the basis of MRI findings, the average distance of the motor areas of the coronary suture - 12.5 mm, and distance the motor areas of the coronary suture identification ES - 19mm, indicate that the difference in distance motor offsets the MRI findings and direct ES, is in the range of 6.5 to 10.7 mm (25). The same authors found an error in the identification of motor areas and the use of neuronavigation procedures ranging from 1.5 to 4 mm, with an additional 5mm by craniotomy and opening the dura mater due to brain shift and highlighting CSF (4, 9).

Our results and review of the literature impose direct electrostimulation as binding intraoperative procedure for all lesions localized in the region of the motor cortex.
